Introduction

There is enough experimental information available now so that a reasonable picture can be formed of the electrons in the outer belt. From Explorer XII we now know there are typically ~10^7 electrons/cm^2-sec in the energy region 40 Kev - 1 Mev in the outer belt[1]. This is a considerably lower flux than earlier estimates had given. The flux does not vary much with position in the outer belt from 25,000 km to 65,000 km and also that flux does not vary much with time. Time variations of x2 or x3 in intensity are seen in the 100 Kev energy range occasionally ranging up to x5 or x7 during August and September, 1961[2]. These variations might be due only to changes in the magnetic field and the associated effects on particles rather than changes in the particle population. The large time variations in flux seen on several earlier experiments are seen only in the high energy (E > 1.6 Mev) group of electrons on Explorer XII. Very likely the large time variations on several earlier experiments involved the high energy electrons also.

At the times of magnetic storms the 100 Kev flux changes as much as x7, but returns to roughly the pre-storm flux in a few days at the end of the storm[2]. All of these features seem to indicate a population of particles that has a quite long lifetime.

It is very important to a complete understanding of the radiation belt to know the lifetime of the trapped particles. When dealing with a steady state population, the only way to easily determine particle lifetimes is by measuring the loss rate from the belt. Knowing the total population of the belt then yields the average lifetime.

Data from Experiments on Discoverer Satellites

We have new information that bears on the lifetime of the electrons in the 100 Kev - 1 Mev energy range. Several instruments have recently been flown on Discoverer satellites. These vehicles orbit at a few hundred kilometers altitude at an inclination of ~82°, so the earth is quite well covered by measurements from these satellites. The instruments that have been flown are: (1) a thin CsI scintillator covered by 2 mils of Be. This counted electrons of E_c > 100 Kev and protons above about 5 Mev, (2) a thick plastic scintillator that counted electrons of E_e > 2 Mev and protons of E_p > 15 Mev, and (3) a ten channel magnetic electron spectrometer[3/] that counted electrons from 80 Kev to 1.25 Mev.

The count rates of the CsI detector are shown in Figure 1 for the Southern Hemisphere. Three types of features are seen here. First, off the coast of Brazil a high count rate is observed which is related to the loss of particles from the inner radiation belt. In this region the earth's surface magnetic field is weak, so that the inner belt particles come closest to the earth here. Secondly, irregular pulses of particles are seen in the auroral zones. From the electron spectrometer we know that these particles are electrons of E_e < 200 Kev and

a considerable fraction of them come essentially directly down the field
lines. That is, the electrons are not trapped and drifting down in
altitude, but rather, they are on their way to earth in one single
bounce.

The third group of particles is the most interesting. About 10°
or 15° subauroral in the South Atlantic we see a large population of
particles. These particles are not uniquely identified as electrons,
but no protons of $E > 3$ Mev are known to exist in this region of space,
so they are almost certainly electrons. These particles show a smooth
spacial distribution, and their population is quite consistant from pass
to pass. They are the leakage from the outer radiation belt being lost
in the Capetown Anomaly[4]. They showed a roll modulation when one of
the Discoverer vehicles tumbled indicating they are probably
trapped particles. These particles were slowly being lost in an orderly
way, quite different from auroral particles which are lost in squirts.

The plastic scintillator shows quite similar behavior in the
Southern Hemisphere (Figure 2). The losses from the inner belt off
Brazil and the loss from the outer belt off Capetown are quite apparent.
The auroral spikes are, however, not seen indicating that the auroral
particles are below the threshold of this detector.

In the Northern Hemisphere the Discoverer results are quite
different. Auroral pulses are seen by the CsI detector (Figure 3) but

_____

[4] A. J. Dessler, Journal of Geophysical Research, 64, 713 (1959)

the other features are not. The scintillator count rate (see Figure 4) does not show any high count rate regions as in the South Atlantic. Count rate contours for the high count rate regions in the South Atlantic are shown on Figure 5 and Figure 6 for the two detectors.

These features of the radiation belts were first seen on low altitude Soviet satellite [5, 6]. Vernov, et al. observed both the high intensity region off Brazil that they identified as mostly protons and related to the inner belt [5] and also a high intensity region in the South Atlantic mostly electrons related to the outer radiation belt [6].

Calculation of the Loss Rate

From these low altitude measurements on the outer belt electrons, we can calculate the rate of loss of particles from the radiation belt. If we have steady state in the radiation belt, then the situation depicted in Figure 7 occurs. Particles are continually injected into the belt. If, as is commonly thought, radial diffusion is a slow process, then the particles are lost from the belt down into the atmosphere as shown in Figure 7. This loss rate can be described in terms of a drifting of particles down into the loss cones and eventually striking the earth.

4

In this calculation of the loss rate, we must assume that coulomb scattering is the dominant loss process. We have measured the particle flux ϕ at altitude h. From this we can get the net motion of particles downwards, the drift flux, D, by

$$D = \left(\frac{\phi}{v}\right) U$$

where v is the particle's velocity and U is a downward drift velocity. The drift velocity U describes the process of particles gradually leaking out the loss zone as the result of coulomb scattering. This is, of course, an average concept and any one particle does not smoothly move downwards in altitude. The first attempts to describe this loss process[1,8] introduced the concept of the velocity of lowering of mirror points, W. Later it was shown that this description of the process was incomplete[9] and a second term Y was needed which would describe the diffusion of the particles. McDonald has shown[10] that for the case of the exponential atmosphere the two terms can be written as

$$U = W + Y = W \left[1 + \frac{H}{\phi} \frac{\partial}{\partial h} (\phi \rho) \right]$$

where H = scale height of the atmosphere and ρ = air density.

[9] R. C. Wentworth, Thesis, "Lifetimes of Geomagnetically Trapped Particles Determined by Coulomb Scattering," Ph. D., University of Maryland, 1960

[10] W. McDonald, private communication

If the electron flux ϕ varies inversely with air density ρ then
$Y = 0$. We know that this situation is roughly true for protons, but
there is no good data on electrons to evaluate Y. For lack of better
information we will take $W = Y$ and $U = 2W$. It would be quite surprising
if the altitude dependence of ϕ were such that $Y > W$, but we must
wait for final information on this.

Using the value of $U = 1.5 \times 10^5$ cm/sec for $E = 200$ Kev for 400 km
altitude, we can obtain D as a function of position from the CsI detector
data. From D we can determine the total loss rate L from the radiation
belt by

$$L = \oint D \, da$$

To get L we integrate D along two lines of constant integral invarient
I, one in the northern Hemisphere and one in the Southern Hemisphere.
This sums up the loss from one "lunoid" of the belt (see Figure 8).
A lunoid is a figure of revolution whose cross section is a lune, the
region between two neighboring field lines, as shown in Figure 8. We
will take two strips 1 cm wide around the earth in order to evaluate L.
The volume of the lunoid whose base is 1 cm wide for $r_o = 2.8 \, r_e$ is
$V = 1.4 \times 10^{20}$ cm^3. L evaluated this way is 2.5×10^7 electrons/sec and
the volume loss rate is $\ell = L/V = 1.5 \times 10^{-13}$ electrons/cm^3-sec.
The only contribution to the integral to get L is from the region of

6

South Atlantic. For a steady state situation the volume loss rate $l = s$, the source strength, that is populating the radiation belt. The source strength s calculated[11] for neutron decay is about $\sim 10^{-13}$ elec/cm^3-sec for the outer belt. This value of s looks very similar to the calculated value of l which indicates that the neutron decay source seems adequate in strength to produce the outer belt electrons.

We can also get from this the average residence time τ of an electron in the radiation belt by assuming steady state and using $L = Q/\tau$ where Q is the total number of electrons in the lunoid

$$Q = \left[\frac{10^7 \text{ elec/cm}^2\text{-sec}}{(2 \times 10^{10} \text{ cm/sec})} \right] 1.4 \times 10^{20} \text{ cm}^3 = 0.7 \times 10^{17} \text{ electrons}$$

We get for $\tau = Q/L = 0.7 \times 10^{17}/2.5 \times 10^7 = 3 \times 10^9$ sec. This time τ is about the same as the estimates of lifetime[12, 13, 14] for outer belt electrons, based on coulomb scattering.

It is somewhat surprising that the loss rate is as small as it seems to be as the result of this calculation. We might expect, on the basis of other experiments, that polar-cap neutrons would

substantially increase the galactic cosmic ray produced neutron source strength. If this were the case, the source strength would be increased above the value of $s = 10^{-13}$.

Comparison of other Experiments with the Discoverer Results

One other experiment measures the outer belt electron loss rate directly and can be compared with our calculation. The count rate of the 213 GM counter on the Injun satellite[15] determines the electron loss rate of electrons of energy $E > 40$ Kev. The angular distribution of the particles observed by this counter over North America is sometimes so wide that the particles are obviously being lost directly into the atmosphere. The loss rate from these observations is much larger than the value calculated here. The average residence time τ of an electron according to the Injun analysis is about 10^4 seconds. The loss of electrons as observed on Injun must be considered to be the result of a catastrophic process; that is, the electron mirror altitude is changed by a large amount in a single bounce period. This must be due to some process other than coulomb scattering.

---

[15] B. J. O'Brien, "Direct Observations of Dumping of Electrons," SUI 62-2

This comparison of Injun and Discoverer results seems inconsistent, but with the help of the electron spectrometer experiment [3] on Discoverer we can understand both experiments.

The spectrometer detects three different and distinct spectra of electrons.

Spectrum (A) is a very sharply falling off function of energy. The intensity decreases a factor of e with increase in about 5 Kev and is only present below 125 Kev. This spectrum is seen almost world wide at some times and other times is not seen at all. Fluxes greater than 10^6 elec/cm^2-sec-ster are seen in a 28 Kev wide channel centered at 94 Kev at some times.

Spectrum (B) e-folds with a change of energy of from 25 to 40 Kev and goes up to about 200 Kev. It is seen prominently in the auroral zone and shows large time fluctuations. A group of particles of $90 < E < 245$ Kev, with similar energy spectrum, with considerably lower intensity is seen in the inner belt loss zone off Brazil and is seen some in the outer belt loss zone off Capetown.

Spectrum (C) usually has a maximum intensity at about 600 Kev and goes up beyond 1.2 Mev. At 200 Kev it is down about x2 from maximum intensity. This spectrum is always seen in the inner belt loss zone off Brazil and with lower intensity in the outer belt loss zone off Capetown. The fact that the spectrometer has lower intensities of the (C) spectrum in the outer belt loss zone than off Brazil may be due to the fact that the look direction of the spectrometer

9

is closer to the direction of the field line. If the angular distribution is pancake shaped, it would be seen less near the direction of the field line. The (C) spectrum is also seen in certain small areas of the Pacific Ocean. It shows a smooth spacial variation and is quite constant in time. The intensity at one place normally is constant to a factor of x2 for long periods.

The fact that there are three different spectra of electrons apparently produced by different processes helps explain other experiments. The Injun experiment[15] that observed catastrophic dumping over North America is quite consistent in spacial extent, time variations and energy and flux with the spectrum (A) of electrons seen on Discoverer. The fact that these electrons are almost all of $E \sim 100$ Kev means that the CsI detector on Discoverer will not see these particles.

The (C) spectrum observed on Discoverer looks quite like the equilibrium electron energy spectrum expected[16, 17, 18] from neutron β-decay, except that it extends to higher energies. This population of particles shows smooth spacial variations and roll modulation indicating the particles are trapped, and the flux is quite

[16] P. J. Kellogg, Journal of Geophysical Research, 65, 2705 (1960)

[17] Lenchek, Singer and Wentworth, Journal of Geophysical Research, 66, 4027 (1961)

[18] Hess and Poirier, Journal of Geophysical Research, to be published

constant in time. All of these facts and also the fact that this spectrum is seen essentially only in the magnetic field anomolies in the South Atlantic strongly indicates that these particles are being lost by coulomb scattering. If other processes were responsible for the particle loss then there would be no reason for the measured flux to be largest in the South Atlantic. The fact that the fluxes of the (C) spectrum are concentrated in the South Atlantic means that the atmosphere controls the loss process. The particles' mirror points come closest to the earth in this region and the particles encounter the densest atmosphere here. This shows coulomb scattering is the dominent loss process.

We can experimentally put a lower limit on the (C) spectrum particle lifetime from the Discoverer data. The particle flux other than in the South Atlantic is $c < 5$ elec/cm^2-sec. Assuming that this flux of particles is all being catastrophically lost as the Injun particles were and therefore D = 5, then we get

$$L = 2 \times 10^{10} \text{ elec/sec.}, \quad l = 10^{-10} \text{ elec/cm}^3\text{-sec and } - = \frac{.7 \times 10^{17}}{2 \times 10^{10}}$$

= .4 x 10^7 sec. The (C) spectrum electron lifetimes are, therefore, longer than .4 x 10^7 sec and probably much longer because the assumptions here are quite extreme.

Conclusions

The following points have come out of this analysis:

(1) There are three separate groups of electrons observed on the Discoverer flights.

(2) The (A) spectrum falls off sharply with energy and does not extend above 125 Kev. It shows large time fluctuations. The Injun experiment that observed direct dumping was quite likely seeing this flux of particles. The source of these particles is not understood.

(3) The (B) spectrum is the spectrum of auroral electrons. A similar spectrum also appears some in the particles lost from the radiation belts indicating that some of the electrons of $E < 200$ Kev in the radiation belt have been accelerated by auroral processes.

(4) Most of the electrons in the radiation belt are of the (C) spectrum type which looks rather like a neutron β-decay spectrum except extending to higher energies. These particles are lost from the radiation belt by coulomb scattering.

(5) The average residence time of an electron in the outer radiation belt is calculated on the basis of coulomb scattering to be 3×10^9 seconds and is measured to be considerably longer than $.4 \times 10^7$ sec. The analysis here is uncertain to x2 or more in two or three places, but the results are probably good to a factor of x5.

(6) The data on the (C) spectrum electrons concerning their energy spectrum, loss rate and lifetime are all consistent with these particles being the result of neutron decay. These particles constitute most of the inner and outer radiation belt electrons.
